Abstract. Since the auroral ionosphere provides an important energy sink for the magnetosphere, ionosphere-thermosphere coupling must be investigated when considering the energy budget of the ionosphere-magnetosphere coupling. We present the first Scandinavian ground-based study of high-latitude F-region ion-neutral frictional heating where ion velocity and temperature are measured by the EISCAT incoherent scatter radar as well as neutral wind and temperature being measured simultaneously by a Fabry-Perot interferometer. A geomagnetically active period ($K_p = 7^- - 5^-$) and quiet period ($K_p = 0^+ - 0$) were studied. Neglecting the neutral wind can result in errors of frictional heating estimates of 60% or more in the F-layer. About 96% of the local ion temperature enhancement over the neutral temperature is accounted for by ion-neutral frictional heating.

Key words: Ionosphere (auroral ionosphere; ionosphere-atmosphere interactions)

1 Introduction and theory

One of the major sinks of magnetospheric energy, provided by the solar wind, is ionospheric Joule heating caused by the dissipation of Pedersen currents. Ionospheric ohmic heating is the second most important sink of magnetospheric energy after the ring current (Akasofu, 1981) and generally amounts to several times greater than that associated with auroral particle precipitation (e.g. Banks *et al.*, 1981; Ahn *et al.*, 1983). A major part of the energy released is deposited in the auroral zone (Kosch and Nielsen, 1995) and can be observed most easily as increased ion temperatures (Schlegel and Collis, 1999). It is important to study ionosphere-thermosphere coupling because ion-neutral

collisional friction is an important loss mechanism in the energy budget of ionosphere-magnetosphere coupling. During a major magnetic storm, Lu *et al.* (1998) showed that about 4% of the solar wind kinetic power (11000 GW) was deposited in the magnetosphere (460 GW), of which about 40% was dissipated in the ionosphere (190 GW).

Incoherent scatter measurements and observations with a Fabry-Perot interferometer are an ideal combination for ionosphere-thermosphere coupling investigations. The former provides information about the ionised component, the latter about the neutral component of the atmosphere. Here we investigate ion-neutral frictional heating in the high-latitude F-region using ion velocity and temperature data obtained with the EISCAT incoherent scatter facility (Rishbeth and van Eyken, 1993), together with neutral winds and temperatures derived from Fabry-Perot interferometer measurements. EISCAT provides height profiles of electron density, electron and ion temperature, as well as the vector of ion velocity in the F-layer from tristatic measurements at 250 km altitude. The Max-Planck-Institut für Aeronomie Fabry-Perot interferometer (Kosch *et al.*, 1997a) is located near Skibotn (69.35°N, 20.36°E), Norway, about 50 km from the EISCAT Tromsø radar site. Observations are made at 630 and 557.7 nm wavelengths, corresponding to the upper (~250 km) and lower (~115 km) thermosphere, respectively (Kosch *et al.*, 2000). Neutral winds and temperatures are derived from the Doppler shift and broadening, respectively, of the selected airglow/auroral emissions (Kosch *et al.*, 1997b). By scanning the instrument to different azimuthal directions (north, south, east, west and vertical), neutral wind vectors with a temporal resolution of about 8–16 min are obtained, depending on the emission intensity.

Ion-neutral dynamics studies at high latitudes have been performed before from satellite measurements (e.g. Killeen *et al.*, 1984, 1991; Killeen and Roble, 1988), with the Chatanika incoherent scatter radar and two ground-based interferometers (Sica *et al.*, 1993) as well as with EISCAT and ground-based interferometers (e.g. Davis

et al., 1995; Lilensten *et al.*, 1992; Farmer *et al.*, 1990; Winsor *et al.*, 1988; Rees *et al.*, 1984). Most of the EISCAT related studies did not measure the neutral temperature directly. There has been only one attempt in the past to measure neutral winds and temperatures directly in conjunction with EISCAT, using a Michelson interferometer (Thuillier *et al.*, 1990), but no further analysis other than simple comparison was done. Ours are the first such combined measurements, using a Fabry-Perot interferometer operating on a routine basis. The effects of the neutral winds on the ionospheric electric fields and the Joule heating rate have been investigated for a long time but from a rather theoretical point of view. Fujii *et al.* (1998) studied the neutral wind contribution to the ionospheric electrodynamics using EISCAT data but with neutral wind related electric fields derived from EISCAT observations only.

In order to calculate ion temperature enhancements over the neutral temperature, resulting from ion-neutral frictional heating, we apply the ion energy equation. The general form of the equation is given by e.g. Schunk (1977). For the assumptions of F-region heights, we use the following approximation made by St.-Maurice and Hanson (1982):

$$3k(T_i - T_n) = m_n |\mathbf{v} - \mathbf{u}|^2 + \frac{m_i + m_n}{m_i} \frac{v_{ie}}{v_{in}} 3k(T_e - T_i) \quad (1)$$

where T_i , T_e , T_n are the ion, electron, and neutral temperatures, respectively, \mathbf{v} the ion drift velocity, \mathbf{u} the neutral wind vector, m_i and m_n are the ion and neutral masses, respectively, v_{in} and v_{ie} are the ion-neutral and ion-electron collision frequencies, respectively, and k is Boltzmann's constant. The difference between the ion and neutral temperature is determined by frictional heating, which occurs whenever there exists a relative velocity between the ion and neutral gas, and also by ion-electron heat exchange. Since the ion-electron collision frequency is much smaller than the ion-neutral collision frequency, the heat exchange term is often assumed to be negligible.

High electric fields cause a non-Maxwellian velocity distribution of the ions and the ion temperature becomes anisotropic (e.g. Gaimard *et al.*, 1998). Since gyrotropic conditions in the F-region exist ($v_{in} \ll$ ion cyclotron frequency), the ion thermal velocity distribution is symmetric with respect to the magnetic field, but the ion temperature parallel to the magnetic field $T_{i\parallel}$ is smaller than the "average" ion temperature $\langle T_i \rangle$ given by Eq. (1) (St.-Maurice and Schunk, 1977, 1979). Neglecting the ion-electron heat exchange term in Eq. (1), the parallel ion temperature can be described by the equation (e.g. St.-Maurice *et al.*, 1999)

$$T_{i\parallel} = T_n + \frac{m_n}{3k} |\mathbf{v} - \mathbf{u}|^2 1.5\beta_{\parallel} \quad (2)$$

where β_{\parallel} is the ion temperature partition coefficient. McCrea *et al.* (1993) give an empirical expression for β_{\parallel} which depends on the momentum transfer collision frequencies for ion-neutral and Coulomb collisions. To a first approximation, β_{\parallel} is a constant depending on the collision model and the ion and neutral composition and remains less than or equal to 2/3.

Both Eqs. (1) and (2) are employed to predict the F-layer ion temperature, using simultaneous EISCAT and FPI measurements for \mathbf{v} , \mathbf{u} , T_e and T_n . The neutral mass m_n is modelled by MSISE-90 (Hedin, 1991). Collision frequencies are calculated after Schunk and Walker (1973) and Kelley (1989) using MSISE-90 model values for the relevant number densities. The predicted T_i are then compared to the values measured directly by EISCAT. Since the ion temperature recovered from the EISCAT CP-1 experiment is $T_{i\parallel}$ rather than $\langle T_i \rangle$, a suitable value for β_{\parallel} has to be assumed. Following St.-Maurice *et al.* (1999), for the oxygen-dominated atmosphere above 250 km, β_{\parallel} should be between 0.18 and 0.25. In the work presented here, calculations of $T_{i\parallel}$ are performed with $\beta_{\parallel} = 0.67$, i.e. no correction for anisotropic ion temperature effects, which are compared with the results obtained with $\beta_{\parallel} = 0.25$.

Since the ionospheric plasma in the high-latitude F-region is predominantly driven by electric fields, the frictional heating can also be described equally as Joule heating produced by the ohmic losses of the Pedersen current $\mathbf{j}_p = \sigma_p \mathbf{E}_{eff}$ with Pedersen conductivity σ_p and effective electric field $\mathbf{E}_{eff} = -\mathbf{v} \times \mathbf{B} + \mathbf{u} \times \mathbf{B}$, taking into account the contribution of the neutral wind dynamo, where \mathbf{B} is the Earth's magnetic field. The height-dependent Joule heating rate is given by $Q_{J,eff} = \mathbf{j}_p \mathbf{E}_{eff} = \sigma_p \mathbf{E}_{eff}^2$. With the help of direct neutral wind measurements we can assess the significance of the neutral wind induced electric field on the local Joule or frictional heating rate at F-region heights.

2 Results and discussion

During the period of 17:30–23:00 UT on 9 and 10 November, 1998, a coordinated EISCAT-FPI experiment was performed. The EISCAT radar was operated with the Tromsø beam parallel to the magnetic field (CP-1 mode) with tristatic measurements of the ion drift at 250 km altitude. The FPI was operated at 630 and 557.7 nm. In this study, only the F-region measurement at 630 nm is used as no EISCAT tristatic measurements were available in the lower thermosphere (corresponding to 557.7 nm). The effective FPI observing height is inferred from the electron density peak height measured by EISCAT, based on the assumption that the maximum emission intensity will be near the height of peak ionisation (Herrero and Meriwether, 1980). The sampling time of the EISCAT measurements is 2 min with a height resolution of 22 km in the F-layer. A 2-point running average in time and a 3-point running average in altitude are used to smooth the data. The FPI measurement scan cycle is about 8 min (30 s integration) on the first night and 16 min (90 s integration) on the second night. The lower resolution on the second night results from longer integration times due to the lower emission intensity. The two nights of observation are characterised by large differences of geomagnetic activity. The first period was very disturbed with $K_p = 7^- - 5^-$, and electric fields up to 60 mV/m, while the second period was very quiet with $K_p = 0^+ - 0$,

and electric fields below 20 mV/m. This permits ion-neutral coupling in the F-layer to be studied under very different geomagnetic conditions.

Simultaneous EISCAT and FPI measurements for 9 and 10 November, 1998, are shown in Figs. 1 and 2, respectively. The variation of magnetic activity is

represented by the Polar Cap Index (Troshichev *et al.*, 1988) in the last panel of each figure. In the top panel measurements of neutral (blue curve) and ion (red curve) temperatures are compared with the neutral temperatures (green curve) modelled with MSISE-90 (Hedin, 1991) and the predicted ion temperatures (black curve)

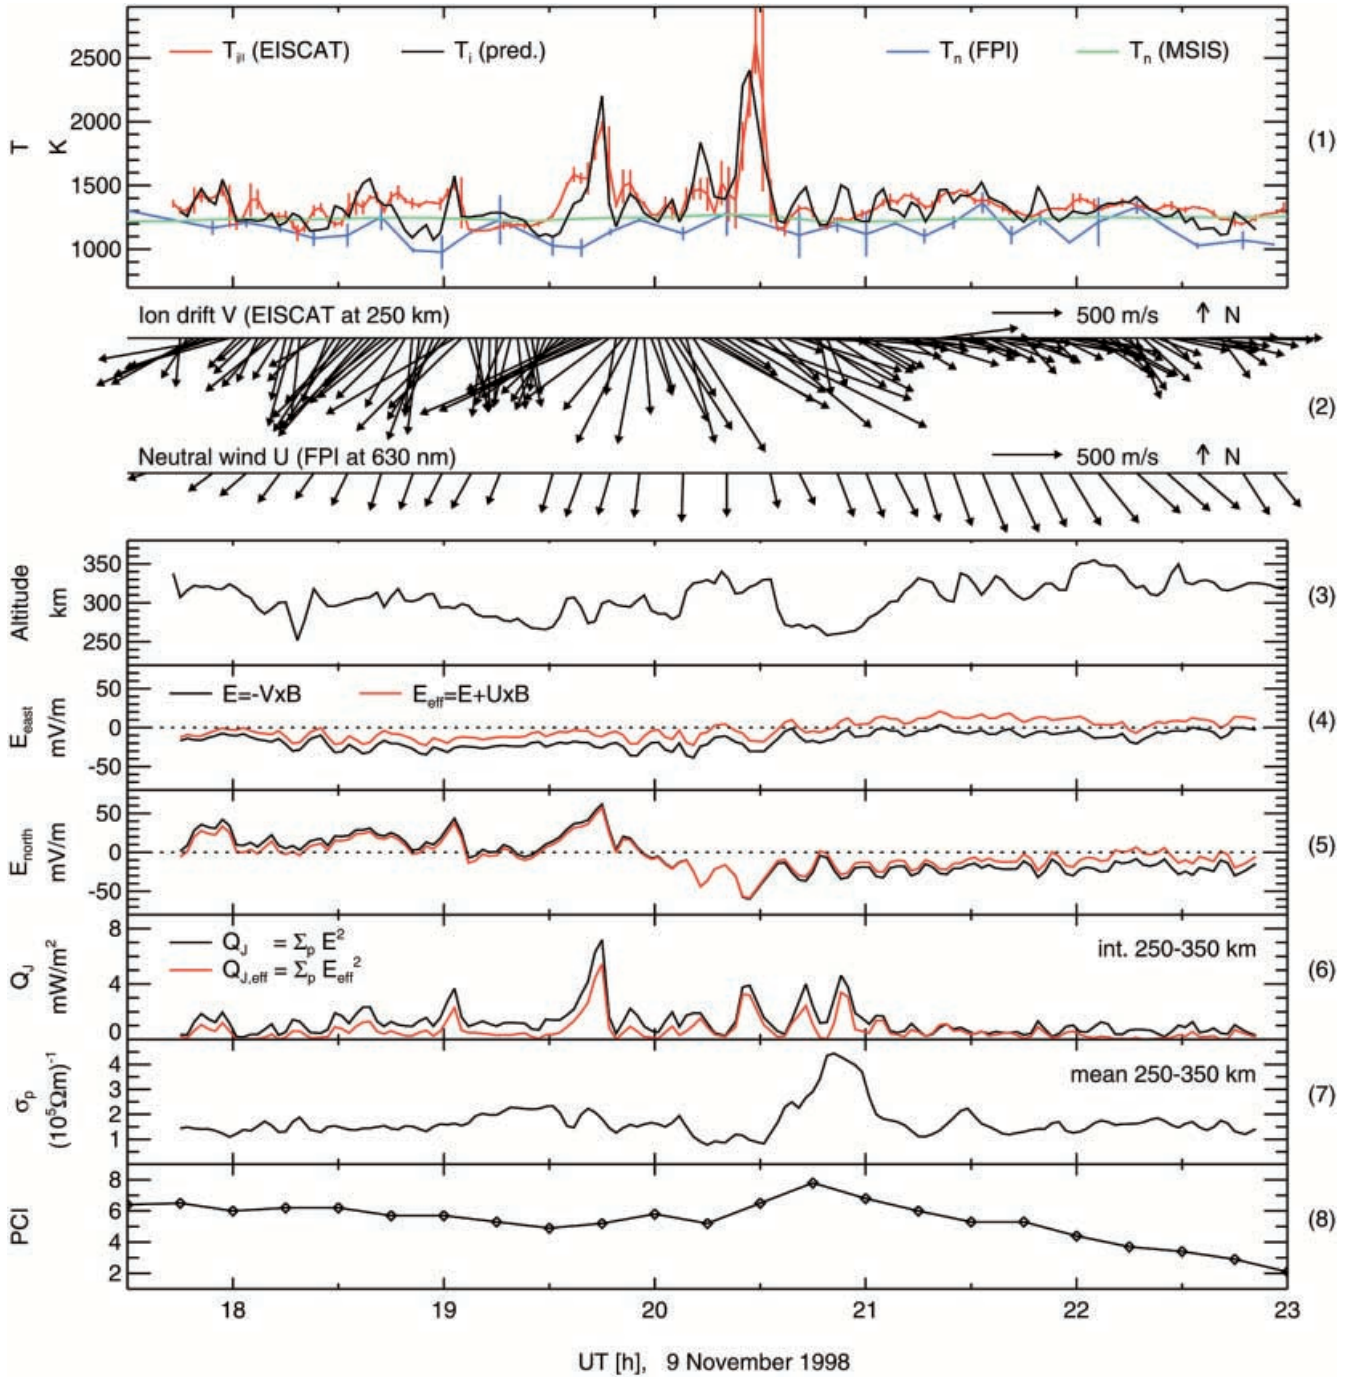

Fig. 1. A composite plot of EISCAT and FPI observations versus universal time, in the F-region, for the geomagnetically active night of 9 November, 1998 ($K_p = 7^- - 5^-$). From top to bottom: a comparison of ion (red curve) and neutral temperature (blue curve) measurements, neutral temperature modelled by MSISE-90 (green curve) and ion temperatures (black curve) predicted from the ion energy Eq. (1) (panel 1); measured ion drifts and neutral winds perpendicular to the

magnetic field (panel 2); the assumed effective FPI observing height at 630 nm and altitude of ion temperature observations (panel 3); the electric field components (panels 4 and 5) and local Joule heating rate (integrated over the range 250–350 km) (panel 6), calculated with (red curve) and without (black curve) the neutral wind contribution, respectively the Pedersen conductivity (averaged over the range 250–300 km) (panel 7); and the Polar Cap index (panel 8)

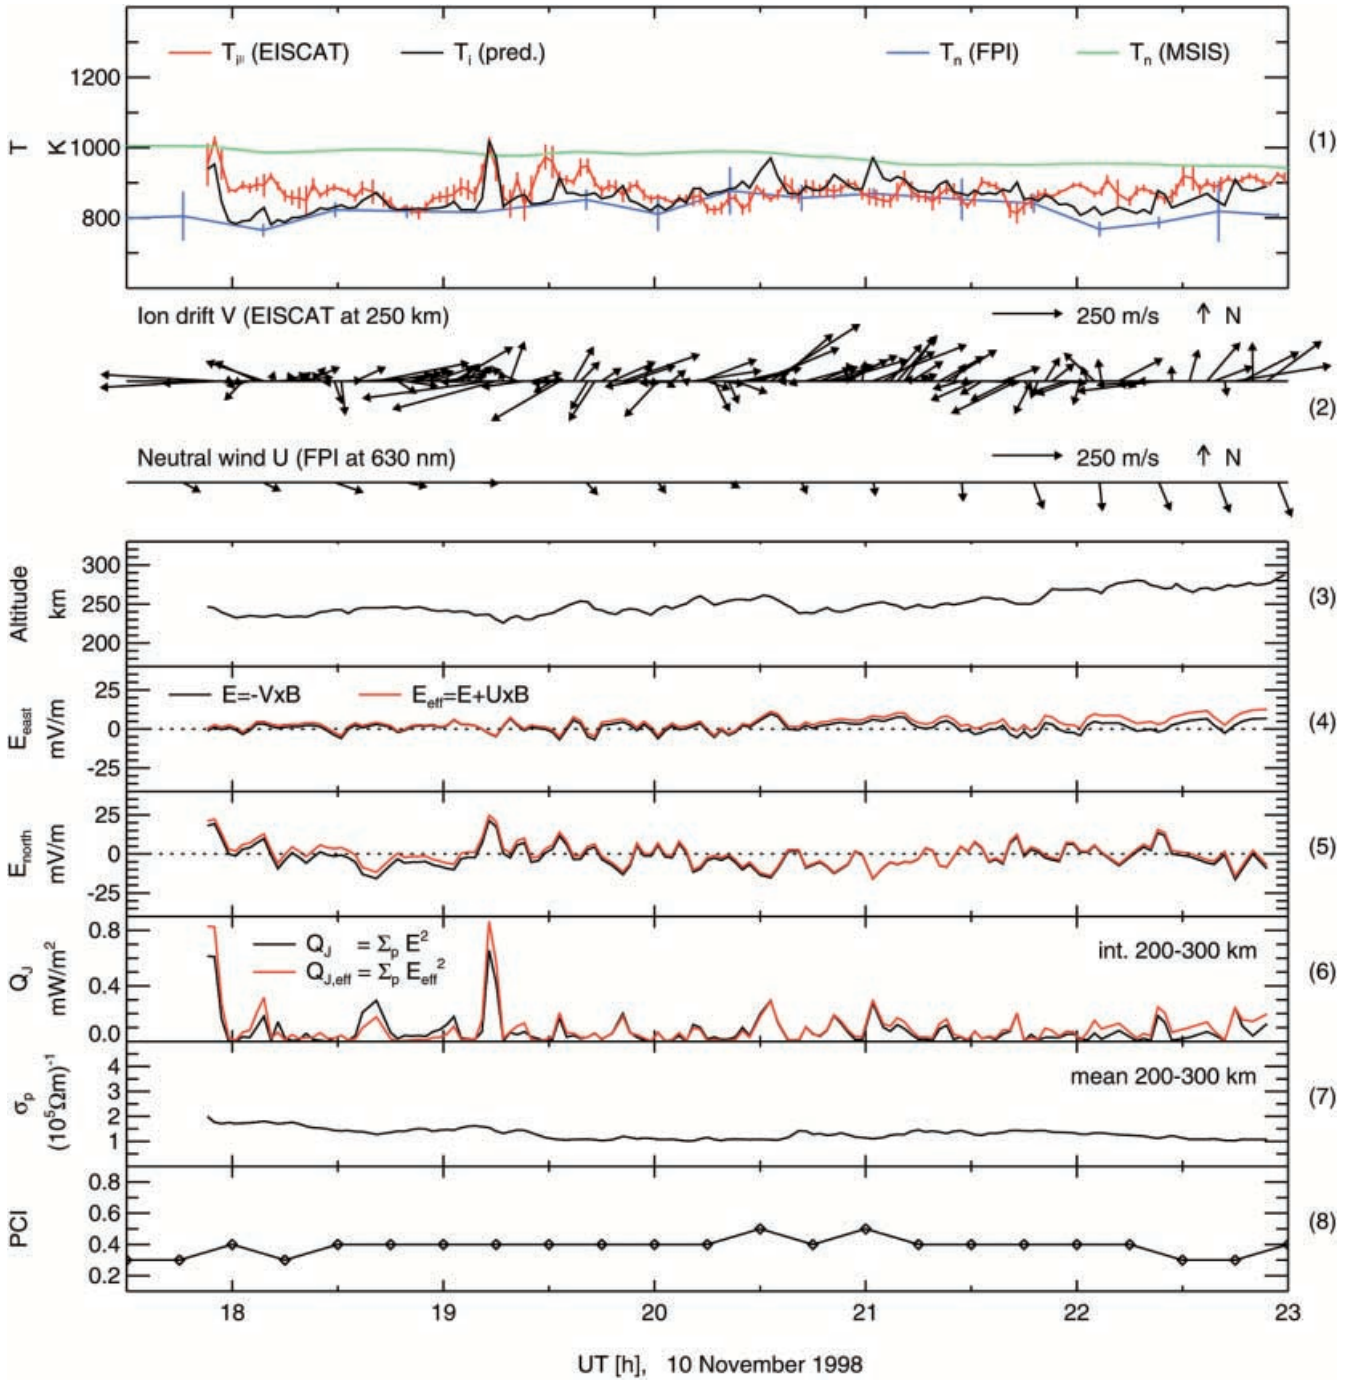

Fig. 2. Same as Fig. 1, but for the geomagnetically quiet night of 10 November, 1998 ($K_p = 0^+ - 0$). The height range for the integration of Q_J and the mean of σ_p has been changed because of the lower $h_m F2$ height

using the ion energy equation 1 (i.e. no correction for anisotropic ion temperature effects). The EISCAT ion temperature, the MSISE-90 neutral temperature and the ion temperature prediction are given for the effective FPI observing height (panel 3). In order to calculate the ion temperature at the EISCAT data points, linear interpolation is used for the neutral FPI measurements. The vertical bars represent the error estimates. The error in T_i is given by the standard deviation of the EISCAT raw data analysis. The error in T_n is estimated by comparing independent fits to the first two FPI fringes.

Table 1 gives an estimate of the averaged absolute measurement uncertainties for the measured parameters.

The FPI neutral temperature is always lower than or equal to the EISCAT ion temperature: this is what is

Table 1. Averaged measurement errors (estimated)

	Temperature	Velocity
EISCAT (ions)	± 20 K	± 60 m/s
FPI (neutrals)	± 100 K	± 15 m/s

Fig. 3. Same as Fig. 1, *panel 1*, but with the parallel ion temperature (black curve) predicted from the ion energy Eq. (2) using $\beta_{\parallel} = 0.25$

expected from the ion energy equation (Eq. 1). For the geomagnetically active period (Fig. 1) MSISE-90 makes a reasonable estimate of the neutral temperature, although deviations of up to 200 K (e.g. 19 UT) do occur when compared to the FPI measurements. The MSISE-90 model fails for the geomagnetically quiet period (Fig. 2), since the predicted neutral temperature level is on average approximately 100 K higher than the ion temperature. The reason for this is not clear, however, the problem must lie in the model as the neutral temperature can not be greater than the ion temperature (see Eq. 1). During the disturbed period (Fig. 1), large enhancements of T_i over T_n , up to 1300 K (e.g. 20:30 UT), occur. These enhancements are well correlated with large differences between the measured ion drift and neutral wind (second panel of Fig. 1), indicating the dominance of frictional or Joule heating. For both observation periods there is good agreement between the measured ion temperature and their prediction from Eq. (1). At times, discrepancies of up to 200 K and 100 K do occur for the geomagnetically active (e.g. Fig. 1, 19:30 UT) and quiet (Fig. 2, 18 UT) periods, respectively. The calculation of ion temperature neglecting the ion-electron heat exchange term in Eq. (1) is not shown here. The same result is obtained using Eq. (2) with $\beta_{\parallel} = 2/3$ (i.e. no correction for anisotropic ion temperature effects). However, the effect of ion-electron heat exchange is small in most cases and never exceeds 90 K.

Figure 3 also shows a comparison of temperatures for 9 November, 1998, where the predicted parallel ion temperature is calculated using Eq. (2) with $\beta_{\parallel} = 0.25$. For nearly the entire period investigated, the prediction is too low compared with the measurement. This strongly indicates that the ion temperature distribution in space is relatively isotropic. This implies a Maxwellian velocity distribution in this case even though the electric field exceeds 30 mV/m on average, peaking up to 60 mV/m. Likewise, for the geomagnetically quiet day (10 November, 1998), anisotropic temperature effects do not occur in the data (not shown).

Figure 4 shows the distribution of the percentage difference between the measured and predicted ion temperature ($\beta_{\parallel} = 2/3$), separated for the magnetically active and quiet days. With a sampling time of 2 min, the total number of sampled values are 149 and 137 for

Fig. 4. Distributions of the percentage difference between measured and predicted ion temperatures for the magnetically active and quiet periods in the F-layer

the active and quiet period, respectively. The distribution for the quiet period (10 November) is somewhat narrower, but for both cases there are two common features despite the relatively low statistical sample. Firstly, the percentage differences are mostly less than $\pm 10\%$ and therefore in the range of our expected measurement uncertainty (see Table 1). Secondly, the distribution maxima lie around $+4\%$, indicating that

the neglected heat sources in the simplified energy equation (Eq. 1), e.g. heat advection and heat conduction (see St.-Maurice and Hanson, 1982), contribute only a small fraction to the measured ion temperature. It is clear, however, that ion-neutral frictional heating is the most dominant F-region heating source, contributing about 96% of the ion temperature enhancement over the neutral temperature on average.

To compare the EISCAT ion temperature with the predicted one, which is based on the FPI measurement, it is necessary to determine the effective observing height of the FPI. The effective observing height is assumed to be one scale height below the electron density peak (H. Rishbeth, private communication) and is shown in the third panels of Figs. 1 and 2. This height is used in the data analysis, except for the ion drift which is fixed at 250 km. Unfortunately, a more reliable method of observing height determination is not available. In contrast to our study, Sica *et al.* (1993) inferred the centroid height of the 630 nm emission, under the assumption that Eq. (1) gives an appropriate description of the ion energy balance. They obtained balance either in the upper thermosphere above 265 km or in the lower thermosphere below 212 km. For periods where the predicted temperature is too low compared with the measured one in our data set (e.g. Fig. 1, 18:45–19:10 UT and 19:25–19:40 UT), the method of Sica *et al.* (1993) would give a balance at lower observing heights than we have determined from the electron density profile. Accordingly, instead of, or in addition to, the neglected heat sources in Eq. (1), the discrepancies could be explained by unforeseen behaviour of the peak emission height. However, there appears to be no evidence of any significant reduction in electron density peak height during 18:45–19:10 and 19:25–19:40 UT on 9 November, 1998. The dominance of frictional heating on ion temperature enhancements over the neutral temperature, particularly for active periods, would be found by both methods of height determination.

The vector plots in panel 2 of Figs. 1 and 2 show the F-region ion drift and neutral wind measurements perpendicular to the magnetic field. It is seen that the ion and neutral velocity vectors follow the same trend on the geomagnetically active day (Fig. 1). Generally, there is a much greater variability in the ion velocities than the neutral wind, which is consistent with satellite observations (e.g. Killeen *et al.*, 1985, 1991). This results from the very much greater density of neutrals over ions. The primary force determining thermospheric circulation is ion-drag (Killeen and Roble, 1984) with the inertia of the neutrals smoothing out the highly variable ion velocities with a time constant of about 1–3 h (Killeen *et al.*, 1984). The eastward and northward components of the electric field are shown in the fourth and fifth panels of Figs. 1 and 2. They are calculated both with (red curve) and without (black curve) the neutral wind contribution ($\mathbf{E}_{\text{eff}} = (\mathbf{u} - \mathbf{v}) \times \mathbf{B}$). Neglecting the neutral wind generally has the effect of overestimating the effective electric field. After ~21 UT on 9 November, 1998, the neutral wind speed exceeds the ion drift magnitude, resulting from the flywheel effect

(Killeen and Roble, 1988). As the geomagnetic activity declines after 21 UT (Fig. 1, panel 8) the ion velocity correspondingly decreases. Now neutral inertial drag is acting on the ions, which is the reverse of the normal circumstance. As a result, especially the eastward electric field is driven by the dominant neutral wind and is even reversed in direction.

The sixth panel of Figs. 1 and 2 shows the local frictional or Joule heating rates $Q_{J,\text{eff}}$ and Q_J , calculated with (red curve) and without (black curve) the neutral wind contribution to the electric field, respectively, in the F-region. The heating rates are integrated over the ranges of 250–350 km and 200–300 km altitude for Figs. 1 and 2, respectively. The integration ranges are selected with respect to the different $h_m F2$ heights during both observation periods, corresponding to the height ranges shown in panel 3. It is seen that neglecting the neutral wind generally results in an overestimation of local Joule heating. On 10 November, 1998, most of the underestimation results from the fact that the ion drifts and neutral winds were generally very different in direction (see Fig. 2, panel 2) which leads to enhanced electric fields in accordance with $\mathbf{E}_{\text{eff}} = (\mathbf{u} - \mathbf{v}) \times \mathbf{B}$. Since the local Joule heating rate is proportional to \mathbf{E}^2 and σ_p (or electron density N_e), the variation with time of the heating rate is somewhat different from that of the ion-neutral temperature difference, which is density independent. The height-averaged Pedersen conductivity σ_p , calculated from EISCAT data, is shown in panel 7 of Figs. 1 and 2.

Figure 5 shows the distribution of percentage differences between $Q_{J,\text{eff}}$ and Q_J , separated for the magnetically active and quiet days. The total number of sampled values is the same as for Fig. 4. The distribution seems to be dependent on magnetic activity. During the active period (9 November), neglecting the neutral wind leads to an average error of about 60%, with the effective ion-neutral frictional heating rate being overestimated. In contrast, during the quiet period (10 November) the percentage differences are distributed over almost the full range between $\pm 100\%$, forming no clear single maximum. Clearly, during both periods of observation presented here, the neutral wind is very important for both qualitative and quantitative considerations.

Kosch and Nielsen (1995) studied E-region statistically averaged Joule heating over Scandinavia using the STARE radar system and a Pedersen conductance model. STARE measures the ionospheric electric field at about 105 km altitude. They found that E-region Joule heating was essentially dependent on the square of the K_p index. It is interesting to compare their results with the present study. For the active day of 9 November, 1998 ($K_p = 5^- - 7^-$), the average expected E-region Joule heating ranges between 8.2 and 16.6 mW/m², which is greater than the F-region heating shown in panel 6 of Fig. 1 for any time. This result is not unexpected, since Pedersen conductivity maximises in the E-layer and Joule heating is proportional to this value. No comparison is made for the quiet day ($K_p = 0^+ - 0$) since STARE has very poor measurement statistics for $K_p < 2$.

Fig. 5. Distributions of the percentage difference between the local Joule heating rates $Q_{Joule,eff}$ and Q_{Joule} in the F-layer, calculated with and without the neutral wind contribution, respectively

It should be noted that, in the analysis of the raw EISCAT data, the standard fit was used which assumes that the ion population above 300 km consists of 100% O^+ and that the ion velocity distribution is Maxwellian. The validity of these assumptions decreases with increasing electric field strength (e.g. Lathuillere and Hubert, 1989). Given the small aspect angle in the case of the CP-1 experiment and that the ion-neutral differential velocities are lower than 1500 m/s ($E \approx 75$ mV/m) in our observation periods, the distortion of the spectra in the magnetic field-aligned direction is expected to be small (e.g. Gaimard *et al.*, 1996). Therefore, non-Maxwellian effects, except for the temperature anisotropy mentioned earlier, are not considered further here. However, for moderate electric fields greater than about 30 mV/m, NO^+ is substantially increased in relation to O^+ in the F-layer (Schunk and Banks, 1976). The ion composition affects the derived ion and electron temperatures and to some extent the electron density, but not the ion velocity. Furthermore, the relative

abundance of N_2 with respect to O is increased from quiet to active conditions. The ion energy balance (Eqs. 1 and 2) depends directly on the neutral mass and is therefore strongly affected by neutral composition changes. The difficulties with composition uncertainties, particularly in the atomic to molecular transition region, are pointed out by St.-Maurice *et al.* (1999). Limiting their study to altitudes greater than 250 km or less than 170 km to avoid this problem, they use the standard EISCAT ion composition model. For the data presented here, electric fields exceeding 25 mV/m only occur on 9 November, 1998, when the observing height lies above 250 km. Nevertheless, for the two short periods of this day, which are characterised by relatively high electric fields, the effects of composition changes on the comparison between measured and predicted ion temperature are estimated below.

During the intervals of 19:30–19:50 UT and 20:10–20:40 UT on 9 November, 1998, the effective electric field peaked at values of about 60 mV/m. First, the effects of ion composition changes are considered: in order to get an estimate of the expected reduction of the $[O^+]/N_e$ ratio, the results of Mikhailov and Schlegel (1998) are applied. From their calculation of the height variations of the ion composition for geomagnetically disturbed periods, we obtain the values $[O^+]/N_e = 65\%$ and $[O^+]/N_e = 80\%$ for a period with an average $E \approx 85$ mV/m and $E \approx 35$ mV/m, respectively, at 300 km altitude. With the formulas given by Alcaydé *et al.* (1996), we calculate the range of the resulting correction factor for the EISCAT standard-fit ion temperature T_i , which gives an enhancement between 5.5% ($E = 35$ mV/m) and 12.3% ($E = 85$ mV/m). Secondly, the effects of neutral composition changes are considered: as mentioned above, the neutral mass in Eqs. (1) and (2) is obtained from the MSISE-90 model. For quiet periods, the MSISE-90 is in good agreement with the model calculations of Fuller-Rowell *et al.* (1991). During F-region storms ($K_p = 6$, which is comparable with the activity level on 9 November, 1998), their calculations for high-latitudes show an enhancement of the mean molecular mass from ~ 19 to ~ 22.5 amu. Applying this correction for the intervals noted above, an enhancement of less than 10% of the predicted ion temperature occurs. As a result, if both ion and neutral composition corrections are applied during the intervals noted above, measured as well as predicted ion temperatures are higher compared with the standard calculations in Fig. 1, panel 1. However, the agreement between measurement and prediction is only slightly affected (the difference being less than 10%). Hence, the effects of ion composition changes can be neglected for this case study since they are within our measurement uncertainty range.

3 Concluding remarks

A study of local F-layer ion-neutral frictional heating effects on ion temperature enhancements over neutral temperature, at high latitudes, has been undertaken

using simultaneous measurements of ion velocity and temperature by EISCAT as well as neutral wind and temperature from a Fabry-Perot interferometer. A geomagnetically active period ($K_p = 7^- - 5^-$) and quiet period ($K_p = 0^+ - 0$) were studied. It is found that the neutral wind generally results in a reduction of the effective ionospheric electric field and resulting Joule or frictional heating. Neglecting the neutral wind can result in local frictional heating being overestimated by about $60 \pm 40\%$ during an active period. During a quiet period there appears to be no clear trend in the percentage difference error estimate.

Ion-neutral frictional heating dominates F-layer ion temperature enhancements over the neutral temperature, accounting for about 96% of the increase on average. The MSISE-90 neutral atmosphere model makes a reasonable prediction of the neutral temperature for active conditions, but fails for quiet conditions when it predicts neutral temperatures exceeding the measured ion temperature by approximately 100 K. For the two nights studied here, there appears to be no substantial evidence that the ion temperature is anisotropic in space for an O^+ dominated ionosphere even though the ionospheric electric field is large at times ($30 < E < 60$ mV/m). The best fit between data and prediction occurs for $\beta_{\parallel} = 2/3$, i.e. no correction for anisotropic effects.

Future investigations of simultaneous E- and F-region observations are planned by additionally using the FPI measurements of the oxygen 557.7 nm emission with EISCAT tristatic measurements alternating between the E- and F-layers.

Acknowledgements. EISCAT is an international scientific association supported by the research councils of Finland, France, Germany, Japan, Norway, Sweden and the United Kingdom. We thank the EISCAT director and staff for running the radar and providing the data.

Topical Editor M. Lester thanks J.-P. Saint-Maurice and S. Maeda for their help in evaluation this paper.
